**Abstract**

We have examined the variations in gene content and sequence divergence that could be associated with symbiotic adaptations in the ectomycorrhizal fungus *Paxillus involutus* and the closely related species *Paxillus filamentosus*. Strains with various abilities to form mycorrhizae were analysed by comparative genomic hybridizations using a cDNA microarray containing 1076 putative unique genes of *P. involutus*. To screen for genes diverging at an enhanced and presumably non-neutral rate, we implemented a simple rate test using information from both the variations in hybridizations signal and data on sequence divergence of the arrayed genes relative to the genome of *Coprinus cinereus*. *C. cinereus* is a free-living saprophyte and is the closest evolutionary relative to *P. involutus* that has been fully sequenced. Approximately 17% of the genes investigated were detected as rapidly diverging within *Paxillus*. Furthermore, 6% of the genes varied in copy numbers between the analysed strains. Genome rearrangements associated with this variation including duplications and deletions may also play a role in adaptive evolution. The cohort of divergent and duplicated genes showed an over-representation of either orphans, genes whose products are located at membranes, or genes encoding for components of stress/defence reactions. Some of the identified genomic changes may be associated with the variation in host specificity of ectomycorrhizal fungi. The proposed procedure could be generally applicable to screen for rapidly evolving genes in closely related strains or species where at least one has been sequenced or characterized by expressed sequence tag analysis.

**Introduction**

Comparative analysis of genome sequence data is an important tool to reveal genomic variations that may be related to phenotypic adaptations to specific environments. By comparing sequences encoding alternative phenotypes, it is possible to reconstruct the genomic pattern of change associated with the shift in phenotype. The observed pattern is then contrasted with what is expected in the absence of natural selection; that is with the expectation of the neutral theory of molecular evolution (Hughes 1999). A fundamental concept of this theory is the molecular clock, which predicts that as long as a protein’s function remains unaltered, the protein’s rate of evolution is approximately constant within different phylogenetic lineages (Kimura & Ota 1974). From this principle, it follows that a detection of change in the rate of evolution of a protein may reveal functional changes associated with adaptive changes in phenotypes.

Another principle governing molecular evolution is that gene duplication followed by functional diversification is the most important mechanism generating new genes and
new biochemical functions (Ohno 1970; Hughes 1999). This prediction has been confirmed by recent analyses of genome sequence data. Thus many genes are members of large gene families and duplicated genes arise at very high rates. Following duplications, new genes usually evolve with rapid changes in their sequences and structures. However, the vast majority of gene duplicates are silenced within millions of years (Lynch & Conery 2000; Long et al 2003). Furthermore, gene duplications and deletions are thought to play a major role in adaptations to various growth conditions including resource-limited environments (Dunham et al. 2002), pathogenesis and symbiosis (Ochman & Moran 2001). Accordingly, identification of divergent and duplicated genes is of major interest when studying genome evolution.

Comparisons of closely related strains or species are particularly informative for identifying adaptive evolution because they hold constant all variables shared by congeners (Harvey & Pagel 1991). However, complete genome sequence data are rarely available for closely related eukaryotes. As an alternative, microarray-based comparative genomic hybridization (array-CGH) can be used as a method for screening the presence of conserved and divergent genes (Dunham et al. 2002; Porwollik et al. 2002; Hinchliffe et al. 2003; Edwards-Ingram et al. 2004). In addition, array-CGH can be used to assess gene duplication and deletions at single-gene resolution in closely related species or strains of organisms (Hughes et al. 2000; Dunham et al. 2002; Pollack et al. 2002).

In this study, we have compared the gene content and patterns of large-scale genome variations in strains of the ectomycorrhizae (ECM) fungus Paxillus involutus using array-CGH. ECM are formed by mutualistic interactions between fungi and the roots of woody plants. The fungal partner obtains photosynthetic sugars from the host plant while in return the plant receives mineral nutrients from the fungus (Smith & Read 1997). Phylogenetic analysis has shown that the ancestors of the ECM homobasidiomycetes were free-living saprophytes and that mycorrhizal symbionts have evolved repeatedly from saprophytic precursors (Hibbett et al. 2000). Paxillus involutus belongs to the suborder Boletineae of the homobasidiomycetes, which is one of the clades of ECM fungi identified by Hibbett et al. (2000). *P. involutus* is widely distributed over the Northern Hemisphere. The species has a wide host spectrum, and forms ECM with a large number of coniferous and deciduous trees (Table 1).

The cDNA microarray used in this study contained cDNA reporters representing 1076 putative unique genes in *P. involutus* and were derived from a collection of expressed sequence tag (EST) clones (Johansson et al. 2004). The array has previously been used for examining divergence in gene expression associated with variation in host specificity in strains of *P. involutus* (Le Quéré et al. 2004). To screen for genes diverging at an enhanced and presumably non-neutral rate, we implemented a simple rate test using information from both the variations in hybridizations signal and sequence divergence to genes in the genome of the homobasidiomycete *Coprinus cinereus*. *C. cinereus* is a free-living saprophyte and is the closest evolutionary relative to *P. involutus* that has been fully sequenced. *C. cinereus* is a member of the suborder Agaricinae,

†The microarray was constructed using PCR-amplified cDNA derived from this strain.
which has been identified as a sister group to the boletoid lineage of homobasidiomycetes (Hibbett et al. 1997). We then asked whether the genes evolving at an enhanced rate typically encode proteins belonging to certain functional classes. Furthermore, we were able to unambiguously detect genes that vary in copy number within different lineages of P. involutus. Interestingly, the host specificity differs between strains within these lineages. Accordingly, the identified genomic changes may be associated with the variation in host specificity of ECM fungi.

Materials and methods

Fungal strains, growth conditions and DNA preparations

Five Paxillus involutus strains and one Paxillus filamentosus strain (Table 1) were grown on cellophane-covered agar plates (Brun et al. 1995). After 7–10 days of incubation at room temperature in the dark, the mycelium was transferred to the surface of Gamborg B-5 basal liquid medium (Sigma-Aldrich Sweden AB) (pH 5.0) supplemented with glucose (2.5 g/L) and incubated for 7–14 days. Paxillus DNA was prepared as described previously (Le Quéré et al. 2002), except that the ultracentrifugation steps were omitted. The DNA was treated with RNase A (Promega) and sonicated to generate fragments ranging between 200 and 2000 bp in size. The DNA samples were purified by phenol–chloroform extraction and with the QiAquick PCR purification kit (Qiagen).

Microarrays and genomic hybridizations

In this study, two different batches of cDNA microarrays (Prints 1 and 2) were used. Both arrays were printed with reporters obtained from a nonredundant set of EST clones, either originating from the P. involutus ATCC 200175 strain (henceforth abbreviated ATCC) or from birch (Betula pendula) (Johansson et al. 2004). Each reporter was replicated in at least quadruplicates on the array. A full description of the Prints 1 and 2 array designs are available from the EMBL-EBI ArrayExpress database (www.ebi.ac.uk/arrayexpress) (Accession nos A-MEXD-184 and A-MEXP-92, respectively). From the entire set of available reporters, the plant EST reporters, 9 EST reporters without any putative origin, and 4 out of 39 reporters corresponding to fungal genomic fragments (polymerase chain reaction (PCR) products from various parts of a 33-kb genomic region of P. involutus contained within a cosmid) (Le Quéré et al. 2002) (Table S1, Supplementary material) were excluded from this investigation. This provided a uniset of 1120 reporters including 1076 EST-derived reporters, 35 cosmid-derived reporters, 1 blank and 8 heterologous and commercial control reporters [ArrayControl, Ambion (Europe) Ltd]. DNA corresponding to the heterologous control reporters were spiked in known amounts into the hybridization extracts prior to the labelling process (Table S2, Supplementary material).

The DNA samples (hybridization extracts) were labelled with either Cy3 or Cy5 (CyScribe Post-Labeling Kit, Amersham Biosciences) and purified using the QiAquick PCR Purification Kit (Qiagen). The samples were eluted in 50 µL nuclease-free water and 20 µg of poly(dA)100·poly(dt)80 was added. Before hybridization, the extracts were evaporated and resuspended in 7.5 µL nuclease-free water. They were then heated to 95 °C for 2 min and incubated at 75 °C for 45 min. Finally, one volume (i.e. 7.5 µL) of microarray hybridization buffer (CyScribe Post-Labeling Kit, Amersham Biosciences) and two volumes (i.e. 15 µL) of formamide were added, mixed and briefly centrifuged before being used for hybridization against the cDNA arrays. Prehybridization of the microarray slides was performed in 50% formamide, 5 x SSC (1 x SSC is 0.15 M NaCl and 0.015 M sodium acetate) and 0.1% SDS at 42 °C for 2 h. The slides were then washed with distilled water, then with isopropanol, and finally dried by centrifugation. The slides were hybridized at 42 °C overnight using a CMT hybridization chamber (Corning Glass). They were then washed twice with 2 x SSC and 0.1% SDS (42 °C), once with 0.1 x SSC and 0.1% SDS (20 °C), three times with 0.1 x SSC (20 °C), and finally with 0.01 x SSC (20 °C). After drying by centrifugation, the slides were placed in a dry and dark chamber until scanning. Altogether, 16 microarray slides and 32 hybridization extracts were used in this study (Fig. 1). Fluorescence intensities were measured using an Axon 4000A laser scanner and converted into digital values using Genepix Pro software (3.0.6.89) (Axon Laboratories). Data images were inspected manually and low-quality spots were excluded from further analysis.

Analysis of hybridization intensities by clustering

The mean background fluorescence was calculated for each slide. After local background correction for each spot, the reporters yielding intensities below twice the background were excluded and the fluorescence of the remaining reporters was multiplied by a correction factor to give a common channel mean of 5000 fluorescence units for each slide. The discarded reporters which had yielded intensities below twice the background were then reintroduced, applying the calculated correction factor. After the normalization step, the mean hybridization intensity was calculated for each fungal strain, for each unique reporter and for each of the two batches of arrays (Prints 1 and 2). The log2-transformed values were then centred by subtracting a fixed value of 12.29, corresponding to the log2 of 5000 (fixed intensity used to normalize the data). We then calculated the ratio (log2) of hybridization.
The log intensities between the test and the reference strains for all gene-specific models of the form:

\[
\text{residual} = \mu + A_s + D_d + (A \times D)_{ad} + \epsilon_{radbps} + (B \times P)_{bp} + \epsilon_{adbps} + \epsilon_{rgad}
\]

Subsequently the residuals were fitted by a normalization model of the form

\[
\text{ANNOVA} = \text{ratio of the fitted Gaussian curve to the observed log2 fold change distribution. The log2 fold change value used as a cut-off to discriminate between conserved and divergent genes was identified as the fold change value closest to the mean of the Gaussian curve where the EPLP value was 0.05 (cf. Fig. 6).}
\]

**Analysis of divergent genes using the EPLP procedure**

The closest homologues for all arrayed Paxillus reporters (genes) were identified in the genome of Coprinus cinereus (www.broad.mit.edu) using the tblastx search tool (Altschul et al. 1990). For any given reporter, we retrieved a cohort of reporters with a similar degree of conservation. The cohort contained 50 reporters having the closest, but lower tblastx bit score and 50 reporters with the closest but higher bit score values. Subsequently, a Gaussian curve was fitted to the main peak of the distribution of the log2 fold changes of the hybridization signals of the conserved genes. The Gaussian fit was chosen such that it has the same height as the log2 fold change distribution and such that it equals the log 2 fold change distribution. The estimated probability of local presence (EPLP) was defined as the ratio of the fitted Gaussian curve to the observed log2 fold change distribution. The log2 fold change value used as a cut-off to discriminate between conserved and divergent genes was identified as the fold change value closest to the mean of the Gaussian curve where the EPLP value was 0.05 (cf. Fig. 6).

**Functional classifications of genes**

For the 1076 putative genes represented on the array, a homology search was carried out using the tblastx algorithm (Altschul et al. 1990) with a threshold value of 14 for extending hits and an E-value threshold of 1e-10 against the UniProt sequence database (Apweiler et al. 2004). Gene Ontology (GO) (Ashburner et al. 2000) and InterPro
annotations (Mulder et al. 2005) were inferred by retrieving information from the UniProt entry corresponding to the best tblastx hit. Using the full GO (www.geneontology.org), all the classified genes were mapped to all their parent terms in the yeast GO Slim (www.geneontology.org/GO.slims). The procedure for assigning \( P \) values to all the links in the GO Slim ontology in Fig. 9 is described in Supplementary material (Table S5). The sizes of the identified InterPro families in the basidiomycete *Phanerochaete chrysosporium* was retrieved from Martinez et al. (2004). A Wilcoxon rank test (Wilcoxon 1945) was used for analysing whether the divergent genes of *P. involutus* were over-represented among large gene families of *Phanerochaete chrysosporium* (Table S6, Supplementary material).

**DNA sequencing**

A selection of 17 EST clones were completely sequenced in both directions by using a pTriplEx2-specific universal forward primer P104 (5'-GGGAAGCGCGCCATTGTGTT-3'), a reverse primer T23V (5'-T23V-3', \( V = A, G \) or C), and template-specific primers. Based on the cDNA sequence information, primers were designed to amplify parts of the corresponding genomic regions in the various strains of *P. involutus* and *P. filamentosus* by PCR (Table 2). DNA sequencing was performed using a BigDye Terminator Cycle Sequencing Kit (Applied Biosystems) and a 3100 Genetic Analyser Sequencer (Applied Biosystems). Sequence assembly and analysis were performed using the program sequencher (Genes Code Corp.) and bioedit (www.mbio.ncsu.edu/BioEdit/bioedit.html).

**Validation of the EPLP procedure**

Nucleotide sequence information for the genes amplified in the various *Paxillus* strains were translated and the protein alignments for each genes were made using clustal w (Thompson et al. 1994). Then the protein alignment was used as a template to align the corresponding nucleotide sequences. Homologous gene sequences from *C. cinereus* were identified using the est2genome software as part of the emboss package (Rice et al. 2000). These were added to the alignment (profile alignment). With the software modeltest, likelihood parameters were estimated (Posada & Crandall 1998). One of them is the gamma-distribution rate which accommodates for among-site

Results and discussion

Initial analysis of fluorescence intensities

Genomic DNA from five strains of \textit{Paxillus involutus} and one strain of the closely related species \textit{Paxillus filamentosus} were isolated and pairwise compared by hybridization on arrays containing cDNA reporters originating from the ATCC strain of \textit{P. involutus} (reference strain) (Table 1, Fig. 1). Two different batches of microarray prints were used in these experiments. At first sight, the hybridization signals varied considerably between the two prints. However, the batch effect was only marginal when comparing the ratios of hybridization intensities (Fig. 2). When the log2 ratios of the hybridization signals were clustered, the ATCC, Pi01SE and Pi08BE strains were clustered into one group, the Maj and Nau strains into another group, and Pi01De at some distance from these two groups (Fig. 2). This partitioning is in agreement with a phylogeny based on ITS sequences, which position the ATCC, Pi01SE and Pi08BE strains into the so-called Forest clade, the Maj and Nau strains into the Park clade of \textit{P. involutus}, whereas Pi01De of \textit{P. filamentosus} falls outside these two clades (Le Quéré \textit{et al.} 2004).

Normalizations of hybridization signals

The hybridization data were further analysed using a mixed-model analysis of variance (ANOVA) as implemented in \textit{sas} (Wollinger \textit{et al.} 2001). In \textit{sas}, like most other procedures for analysing microarray data, the hybridization signal intensities are converted to log2 scale and each data point is normalized by subtraction of the array mean log2 ratio value in order to centre the distribution on zero. In Fig. 3, the distributions of the resulting log2 fold changes in the hybridization signals for the sample strains relative to the reference strain of \textit{P. involutus} have been plotted. As expected, the distributions of the fold changes comparing strains within the Forest clade (ATCC/Pi08BE and ATCC/ Pi01SE) were almost identical and the main peaks were centred on zero. Similarly, the distribution comparing the two Park strains (Maj and Nau) was centred on zero (Fig. 3, inserted panel). In contrast, when comparing the ATCC strain with the phylogenetically more distant strains within the Park clade as well as \textit{P. filamentosus} (ATCC/ Maj, ATCC/Nau and ATCC/Pi01De), the main peaks of the distribution plots were shifted to the right (upwards). The shift is due to the presence of a large tail of divergent genes with weak hybridization signals.

In CGH experiments, the main peak should primarily consist of conserved genes. One way for the identification of the correct main peak position is to plot the distribution for the most conserved genes within the various strains. An alternative method for determining the correct position of conserved genes within the fold-change distribution curve is by using hybridization ratios for a set of heterologous reporters (in this study, a total of 8). Both methods indicate that the main peak of the two Park strains (Maj and Nau) should be centred at a log2 fold change value relative to the ATCC of 0.7, whereas that of the Pi01De strain at 1.0 (Fig. 3). Consequently, the log2 fold change values reported below for the ATCC/Maj and ATCC/Nau comparisons have been shifted by −0.7, whereas the fold change values for the ATCC/Pi01De comparison by −1.0.

Sequence divergence and gene copy numbers

In CGH experiments, the variation in hybridization signals depends on several factors, including sequence divergence between the sample and reference DNA, and differences in gene copy number (Wu \textit{et al.} 2001; Hinchliffe \textit{et al.} 2003). To investigate how sequence divergence affected the hybridization signals in our study, 17 loci were sequenced.
in the different strains of Paxillus (Table 2). Depending on the position of the PCR primers, the regions analysed covered 20–84% of the predicted exons. Considering data from all genes and all pairwise comparisons, a weak correlation ($r^2 = 0.30$, $P < 0.02$) was found between sequence identity and log$_2$ fold changes in hybridization signals (Fig. 4).

Further insight into the source of variation was achieved by analysing the data of strains from a single clade and those from two different clades separately. Analysis of the strains of the Forest clade showed that all genes except ptrA displayed at least 97.7% sequence identity, and their log$_2$ fold changes in hybridization signals varied between −0.3 to +0.3. The log$_2$ fold change value for ptrA when comparing ATCC/Pi01SE was significantly outside this narrow range (0.78, corresponding to an antilog fold change value of 1.9) which suggest that this gene is also duplicated in Maj relative to the ATCC strain.

The variations in sequence identity and hybridization signals were considerably larger when contrasting the ATCC strain with strains from other clades. When comparing data for the ATCC strain and the two Park strains, one outlier was identified, namely the ppiA gene. The log$_2$ fold changes in hybridization signals for ppiA when comparing ATCC/Maj and ATCC/Nau were in both cases −0.7, a value that could be expected for genes having a sequence identity in the range 92–96%. However, the sequence identity for ppiA was found to be 100% and all information considered we classify ppiA as putatively duplicated. Excluding ppiA from the analysis, the linear correlation coefficients of the relationship between sequence identities and log$_2$ fold changes for all genes included in the pairwise comparisons of ATCC/Maj and ATCC/Nau were 0.62 ($P < 0.03$) and 0.64 ($P < 0.02$), respectively. In P. filamentosus, only 10 of the 17 loci could be investigated, presumably due to the low sequence identity between the primers used and the corresponding genes in Pi01De. Furthermore, the linear correlation coefficients of the relationship between sequence identities and log$_2$ fold changes for the PCR-amplified genes in the pairwise comparisons ATCC/Pi01De were not significant.

The above analyses suggest that when comparing closely related strains within the Forest or Park clades, respectively, the fold changes in CGH hybridization signals will primarily be associated with differences in gene copy numbers and not sequence divergence. In contrast, when comparing strains from different clades, the variation in hybridization signals can be related to both sequence divergence and copy number differences. To distinguish between these two processes, information on both hybridization signal intensities and sequence divergence are needed.

**Identification of locally divergent genes using the EPLP approach**

To screen for genes diverging at an enhanced rate within the lineage of *P. involutus*, we developed a simple rate test using information from both variation in hybridization signals and sequence similarities to the basidiomycete *Coprinus cinereus* (Fig. 5). Basically, the hybridization signals for any given gene is compared to the signals of genes displaying a similar degree of sequence similarity to *C. cinereus*. An algorithm that depends on the shape of the signal-ratio distribution curve for this cohort of genes provides an estimate (EPLP) of the degree of divergence (Fig. 6).

Using a EPLP cut-off value of 0.05, the numbers of locally divergent genes identified in the pairwise comparisons between strains from the three lineages of Paxillus, the ATCC/Park clade (average Maj and Nau) (Fig. 7A), the ATCC/P. filamentosus (Fig. 7B) and the Park clade/P. filamentosus (not shown) were 106, 64 and 102, respectively. In total, we identified a cohort of 177 genes that were locally divergent according to this procedure in at least one of the three comparisons made (Table S3, Supplementary material). The EPLP algorithm is similar to the algorithm used within the so-called GACK procedure for analysing array-CGH data (Kim et al. 2002). Like other more traditional methods to analyse CGH array data (Porwollik et al. 2002; Hinchliffe et al. 2003), GACK categorizes genes as being
Rapidly Evolving Genes in *Paxillus*

variable or conserved solely on basis of the hybridization signal. In GACK the signal-ratio distribution curve is analysed for all reporters and one EPP (estimated probability of presence) function is calculated that is fixed for all genes. Using an EPP cut-off value of 0.05, we identified a cohort of 195 genes that were divergent according to the GACK procedure. One hundred forty-one of these were also identified as divergent using the EPLP method. However, 36 out of the 177 genes classified as divergent using the EPLP procedure were not identified as divergent using the GACK procedure. These included mainly genes displaying medium to high sequence similarities to *C. cinereus* (Fig. 7).

The EPLP methods’ ability to predict genes evolving at an enhanced rate was validated using information from the 17 sequenced loci (cf. Table 2). The sequences were analysed using a procedure that is based on the comparison of phylogenetic branch lengths of orthologous proteins from three species (Jordan et al. 2001). Adopted to our data set, the length of the branch separating the ATCC strain and *P. involutus* was compared with the sum of the branch separating the ATCC strain and the sample strain (distance ATCC, sample). Consistent with the rate-constancy prediction of neutral evolution, the (distance ATCC, sample)/distance ATCC, sample) ratio should be approximately constant. Accelerated evolution should be manifested by a low ratio. The sequence- and the EPLP-based measures of accelerated evolution were indeed related (Fig. 8). The EPLP method

---

**Fig. 5** The EPLP screen for identifying locally divergent genes. (A) represents an organism with a fully sequenced genome located outside the clade of strains analysed by CGH. (B) here is the reference strain, which is also the strain used for the construction of the microarray. (C) is a closely related sample strain analysed by CGH hybridizations. In our experiments (A) was the basidiomycete *Coprinus cinereus*, which is the closest evolutionary relative to *Paxillus involutus* that has been fully sequenced. (B) was the ATCC strain of *P. involutus* and (C) was other strains of *P. involutus* or *Paxillus filamentous*. The distance of genes between (A) and (B) is estimated by using the *tblastx* algorithm. The divergence of genes between (B) and (C) is measured by CGH analysis. In the screen, the observed CGH fold changes for any given gene is compared with the fold changes from a cohort of genes displaying a similar distance to the outgroup. This cohort contains approximately 100 genes having a similar *tblastx* bit score as the analysed gene. An algorithm that depends on the shape of the signal-ratio distribution curve for this cohort of genes provides an estimate (the estimated probability of local presence, EPLP) of the degree of divergence (Fig. 6). Shown is the hypothetical evolutionary relationship between three genes i, j, and k. Sequence comparisons between (A) and (B) show that i and j have the same overall evolutionary rate, while k evolves faster. Analysis of the CGH hybridization signals between (B) and (C) indicates that j and k are more divergent than i. Note that the position of the internal node along the branch separating strains B and C from A is not known, as the distance between A and C has not been determined. The EPLP procedure will select j but not k as evolving at an enhanced rate. According to the neutral theory of molecular evolution, a shift in the rate of evolution may indicate an alteration in the selection pressure on the genes.

---

**Fig. 6** Application of the EPLP algorithm. The method is illustrated here for the *rabA* gene (cf. Table 2), which has a *tblastx* score of 105 against *Coprinus cinereus*. The solid line shows the distribution of log₂ fold change in hybridization signals between Park and ATCC for 102 genes with a similar *tblastx* score against *C. cinereus* as for the *rabA* gene. The 102 genes had a *tblastx* score from 95 to 117. This is the smallest interval containing at least 50 genes with a smaller *tblastx* score than *rabA*, and also genes with a larger *tblastx* score. The dashed line shows a normal curve fitted to the main peak of the fold distribution curve of the 102 genes. This normal curve represents the expected local log₂ fold distribution of genes which are conserved to the same degree as the *rabA* gene. The estimated probability of local presence (EPLP), marked as a dotted line, shows the expected distribution density (dashed line) divided by the real density of genes (solid line). The *rabA* gene has a log₂ fold change Park/ATCC of −1.14 and is located in the tail of the divergent genes. The EPLP value for *rabA* is 0.001, which is smaller than the cut-off value of 0.05 used to separate conserved and variable genes. Thus *rabA* was classified as a locally divergent gene.
when comparing the ATCC and Maj strains predicts that two genes (rabA and gpiA) were evolving at an enhanced rate. The genes rabA and gpiA were also among those having the lowest \((\text{dist}_{\text{ATCC, } C. \text{ cinereus}})/(\text{dist}_{\text{ATCC, samples}})\) ratio. Note that rabA and gpiA were not identified as being divergent using the GACK procedure. The EPLP procedure appeared to fail to detect two genes with low branch lengths ratios, namely gsta and calA. For gsta the normal distribution is not appropriate (Fig. S2, Supplementary material). The calA gene is one of the most conserved genes comparing P. involutus and C. cinereus. Thus only a few mutations in this gene can affect the ratios of the branch lengths significantly. Such small changes could presumably not be detected by CGH analysis. The above analysis indicates that the EPLP procedure could be used for screening genes diverging at an enhanced rate. However, it should be possible to optimize the algorithm further given a larger set of genes with an a priori known sequence history.

**Orphans**

The genomes of fungi and other organisms contain a significant portion of genes that exhibit no significant similarity to protein sequences present in databases (Tunlid & Talbot 2002). Such orphans may represent genes whose phylogenetic distribution is restricted to certain evolutionary lineages. Orphan genes might also represent genes that rapidly diverge between closely related strains or species.

From a total of 1076 Paxillus gene representatives on the array, 382 showed a tblastx score below 45 when compared to C. cinereus. These orphans varied in hybridization signals and represented both conserved (large \(\log_2\) fold change values) and variable genes (small \(\log_2\) fold change values) (Fig. 7). Since the EPLP procedure cannot be used for analysing genes in cohorts displaying low similarity scores to genes in other organisms, other methods are needed to discriminate between conserved and variable orphans. In the Supplementary material, we show that the distribution of fold changes for the well-conserved genes can be used to estimate an upper number of conserved orphans (Fig. S1, Supplementary material). In total, 52 orphan genes might be just as conserved between the Park and Forest clades as the genes showing a tblastx score against C. cinereus of 100 or above (for Pf01De/ATCC, the corresponding number was 44). Conserved orphan genes with very low divergence rates have also been identified in Drosophila (Domazet-Loso & Tautz 2003). The authors proposed that these slowly evolving orphan genes might represent genes that have evolved to perform lineage-specific functions.

**Functional classification of divergent genes**

The locally divergent genes showed an under-representation of genes predicted to be involved in protein biosynthesis and those encoding structural molecules (Fig. 9A). Both of these categories included ribosomal proteins. In contrast, the cohort of locally divergent genes was over-represented by orphans, proteins predicted to be located at membranes and those involved in transport and lipid metabolism. The predicted membrane proteins...
displayed significant sequence similarities to several larger families of transport proteins (Table 3): the mitochondrial carrier proteins (Vozza et al. 2004), the drug-resistant subfamily of the major facilitator superfamily (Goffeau et al. 1997), the MAPEG (membrane-associated proteins in eicosanoid and glutathione metabolism) superfamily (Jakobsson et al. 1999), and the ELO, GNS1/SUR4 family which is involved in long-chain fatty acid synthesis (Rossler et al. 2003). Among the cohort of locally divergent genes were also genes displaying sequence similarities to thioredoxins, thiol peroxidases and glutathione S-transferases. These components of the thioredoxin and glutathione/glutaredoxin system are important for the regulation of the intracellular redox status and the detoxification of oxidation products generated in various defence reactions (Grant 2001). Among variable genes were also a gene showing similarities to members of the cytochrome P450 gene family, which are important in the oxidative metabolism of endogenous and xenobiotic compounds (Nelson 1999). Notably, orphans, genes whose products are located at membranes, or genes encoding for components of stress/defence reactions are also known to evolve at an accelerated rate in other organisms including bacteria and mammals (Jordan et al. 2001).

</table>
The locally divergent genes were also over-represented (P < 0.01) by genes being homologous to members within large gene families identified in the basidiomycete \textit{Phanerochaete chrysosporium} \cite{Martinez2004} (Table S6, Supplementary material). Several of these large gene families have been shown to be rapidly expanding when comparing lineages of more distantly related eukaryotes \cite{Lespinet2002,vanNimwegen2003}. Among them are the major facilitator superfamily transporters, the cytochrome P450 family hydroxylases, and the glutathione S-transferases.

\textbf{Gene duplications}

To identify genomic differences that could be associated with variations in host specificities, the genomes of the closely related Park strains Maj and Nau were compared. The Maj strain forms ECM with birch and poplar, while Nau is incompatible with these trees \cite{Gafur2004,LeQuere2004}. The log$_2$ fold changes for Maj and Nau relative to the ATCC strain are shown in Fig. 10. Most of the reporters were scattered along the diagonal and thus had highly similar hybridization signals in Maj and Nau. However, there were 21 outliers with log$_2$ fold changes > 0.5 or < 0.5, which indicate that the genes are found in different copy numbers in the two strains. Among these putatively duplicated genes, 14 were identified by EST-derived reporters whereas 7 by cosmid-derived reporters (Table S4, Supplementary material).

Only 2 out of the 14 duplicated genes identified by EST-derived reporters displayed significant sequence similarities to proteins in the GenBank nr protein database \cite{Benson2005}. One of them corresponded to the sequenced loci ptrA (Table 2). The ptrA gene translates into a polypeptide of 185 amino acid residues that shows a high sequence identity (43\%) to Pho88p in \textit{Saccharomyces cerevisiae}. Pho88p is a putative membrane protein involved in inorganic phosphate transport and regulation \cite{Yompakdee1996}. The second duplicated gene (corresponding to the EST clone CD274497) showed a significant similarity to a hypothetical protein in \textit{Neurospora crassa}. The 7 cosmid-derived reporters that indicated variation in copy number between Maj and Nau all originate from one continuous 3.2-kb genomic region, in positions covering the putative ORF PiC1-11 and adjacent DNA regions (Table S1, Supplementary material). PiC1-11 displays a high sequence similarity to a WD40 repeat motif \cite{LeQuere2002}. This domain acts as site for interaction with other proteins, and there are 102 proteins in \textit{S. cerevisiae} with at least one copy of this motif (IPR001680).

We have previously shown that approximately 66 (6\%) of the arrayed genes are differentially expressed in Maj and Nau following the contact with the roots of birch seedlings \cite{LeQuere2004}. Notably, none of the duplicated genes identified in this study were among these differentially expressed genes. Thus, the differences in expression levels cannot be explained by differences in gene copy numbers. Most probably, the observed differences in expression levels are due to variation in promoter elements or levels of transcription factors.

An analysis was also performed to identify duplicated genes between strains of the Forest clade. In total, we identified 56 genes and one cosmid-derived fragment that were found in different copy numbers in at least one of the three pairwise comparisons made between ATCC/PI01SE, ATCC/PI08BE, and PI01SE/PI08BE. Notably, six of these duplicated genes including ptrA were among the genes that also varied in copy number in the comparison between Maj and Nau. Altogether, a cohort of 64 genes was identified as being duplicated in at least one of the four

\*The table lists 27 genes that were identified as being locally divergent (Figs 5–7). Only genes found to be significantly different in at least two of the three pairwise comparisons and displaying a significant homology to proteins in the UniProt database \cite{Apweiler2004} are listed. A full list of locally divergent genes (177 in total) can be found in the Table S3 (Supplementary material). GO annotations \cite{Ashburner2000} were inferred by retrieving information from the UniProt entry. The underlined gene was identified as duplicated within the clades analysed (Table S4, Supplementary material). Genes in bold were characterized by DNA sequencing (cf. Table 2).

\section*{Acknowledgments}

Hepper for valuable discussions and suggestions.
Fig. 10 Identification of genes being duplicated in the compatible strain Maj and the incompatible strain Nau (i.e. not infecting birch or poplar). The scatter plot shows the log₂ fold change in hybridizations signals of Maj relative to ATCC (reference strain) vs. the log₂ fold change of Nau relative to ATCC, for 1019 reporters (990 EST and 29 cosmid-derived reporters). The dotted line is the diagonal showing genes with almost identical hybridization signals in Maj and Nau. The position for each gene along the diagonal is a measure of its divergence between the two Park clade strains Maj and Nau relative to the ATCC strain of the Forest clade, with the most divergent genes scattered towards the lower left corner of the plot. The dotted lines at \( y = x + 1 \) and \( y = x - 1 \) correspond to a log₂ fold change between Nau and Maj of 1 and −0.5, respectively. Genes that have been duplicated in Nau relative to Maj or vice versa are expected to scatter along these lines. Indicates nonduplicated genes (in total 976); duplicated genes (14); non duplicated cosmid-derived reporters (22); duplicated cosmid-derived reporters (7); duplicated genes in the Forest clade (49); duplicated genes in both the Forest and Park clades. All duplicated genes identified to be duplicated in the analysed Paxillus strains are listed in the Supplementary material (Table S4).

Conclusions

Due to the fact that the costs for EST sequencing and the fabrication of microarrays are rapidly decreasing, we foresee that in the near future DNA microarray analysis will become a common tool for comparing genome composition in many organisms. Here we present several novel procedures for the analysis of such data. We suggest methods for the normalization of hybridization data that correct for the presence of a large number of variable genes yielding weak signals, which typically complicates CGH analyses. We have shown that the hybridization signal in the CGH experiments depends on both sequence divergence and gene copy number. When comparing closely related strains, the fold changes in CGH hybridization signals will primarily be associated with differences in gene copy number and not sequence divergence. In contrast, when comparing more distantly related strains, the variation in hybridization signals can be related to both sequence divergence and gene copy number. To distinguish between these two processes, information on both hybridization signal intensity and sequence divergence are needed.

We developed a simple rate test, the EPLP procedure, to screen for genes diverging at an enhanced rate. Such changes in the rate of evolution may indicate cases of functional diversification associated with adaptations. The comparison is made by contrasting the observed fold change in hybridization signal for each gene with the signals from a cohort of genes displaying a similar degree of sequence similarity to an outgroup organism. In principle, any organism with a fully sequenced genome can be used as an outgroup as long as it is more distantly related than the species or lineages being examined by CGH. However, the genomes should be close enough to avoid saturation of nucleotide substitution. Presently, the CGH-based procedure for detecting non-neutral evolving genes has only been validated using sequence data from a limited set of genes. In fact we observed a correlation between the CGH-based measure of non-neutrality and a standard phylogenetic analysis. The analysis also indicated that it should be possible to further optimize the algorithm given a larger set of genes with an a priori known sequence history. In any case, the ‘candidates’ identified by the EPLP screen should be sequenced to verify their rate of divergence and to identify possible selection mechanisms acting on the genes.

The developed procedures were used to screen for duplicated and rapidly evolving genes in strains of the ECM fungus Paxillus involutus. Approximately 17% of the printed genes were detected as rapidly and presumably non-neutrally evolving within P. involutus. Furthermore, 6% of the analysed genes varied in gene copy numbers. The cohort of divergent and duplicated genes showed an over-representation of orphans, genes whose products are located at membranes, and genes encoding for components of stress/defence reactions. Some of the identified genomic changes may be associated adaptations to the symbiotic lifestyle, including variations in host specificity.
of ECM fungi. However, due to the fact that there are other, more closely related species to Paxillus than Coprinus cinereus that are nonmycorrhizal, part of the detected genomic changes might be associated with adaptations to nonsymbiotic growth.
